(Received 12 February 2013; published 20 May 2013)

Recent data from the WMAP, ACT and SPT experiments provide precise measurements of the cosmic microwave background temperature power spectrum over a wide range of angular scales. The combination of these observations is well fit by the standard, spatially flat ΛCDM cosmological model, constraining six free parameters to within a few percent. The scalar spectral index, ns, equal to 0.9690 ± 0.0089, is less than unity at the 3.5σ level, consistent with simple models of inflation. The damping tail of the power spectrum at high resolution, combined with the amplitude of gravitational lensing measured by ACT and SPT, constrains the effective number of relativistic species to be Neff = 3.28 ± 0.40, in agreement with the standard model’s three species of light neutrinos.

I. INTRODUCTION

It has long been appreciated that the cosmic microwave background (CMB) power spectrum contains enough information to precisely determine the standard model of cosmology [1–4]. This promise has been realized through a series of increasingly sensitive experiments, most recently with the WMAP satellite’s nine-year full-sky observations [5,6] and the arcminute-resolution maps from the Atacama Cosmology Telescope (ACT) [7–9] and the South Pole Telescope (SPT) [10,11]. The combination of these measurements probes the temperature power spectrum on angular scales ranging from 90 degrees to 4 arcminutes, scales at which the primary cosmological temperature fluctuations dominate. The primordial fluctuations are well approximated as a Gaussian random field [5,12], but ACT and SPT have also detected the non-Gaussian features due to gravitational lensing of the microwave radiation by the intervening large-scale structures [13,14]. In this paper we present a joint analysis of the ACT, SPT, and final WMAP nine-year power spectra to obtain an estimate of the cosmological parameters from microwave background data alone.

II. DATA AND ANALYSIS METHOD

In Fig. 1 we show the compilation of CMB temperature power spectra used in this analysis. At large angular scales
we use the temperature and polarization data, and associated likelihood, from the nine-year WMAP analysis (hereafter WMAP9) [6]. This measures the Sachs-Wolfe plateau and the first three acoustic peaks, \(2 < \ell \leq 1000\). At smaller scales, \(500 < \ell < 3500\), we use data from ACT and SPT.

Here we follow the method introduced in Ref. [8] to estimate the primary CMB bandpowers from both sets of spectra, marginalizing over the possible additional power from Galactic and extragalactic emission, and the Sunyaev-Zel’dovich effects. We use a Gibbs sampling method to simultaneously estimate CMB bandpowers and a set of ten secondary parameters. For ACT we extract primary CMB bandpowers from the 148 and 218 GHz auto and cross power spectra from two regions (ACT-E and ACT-S [7]) of the sky [15], taking the multifrequency bandpowers in the range 500 < \(\ell < 10000\). We include SPT 150 GHz data [10] from 650 < \(\ell < 3000\), and marginalize over a common model for secondary components [17]. We impose a Gaussian prior of \(12.3 \pm 3.5 \mu K^2\) at \(\ell = 3000\) on the SPT radio source Poisson power, having subtracted 7 \(\mu K^2\) of cosmic infrared background Poisson power, treated separately in our likelihood, from the total expected Poisson level [10,18]. The resulting ACT and SPT lensed bandpowers are shown in Fig. 1, and the secondary parameters are consistent with those reported in Refs. [8,9]. The errors shown are the diagonal elements of the covariance matrix, with the SPT calibration error removed for consistency with ACT. The full covariance matrix includes correlations due to foreground uncertainty, beam error, and the overall calibration for SPT.

We then construct an ACT + SPT likelihood from these CMB bandpowers, which can also be used for each experiment on its own. This is a Gaussian distribution using 42 data points from ACT (21 each from ACT-E and ACT-S) and 47 from SPT, with an associated covariance matrix. For ACT we only use \(\ell < 3500\) bandpowers in the likelihood, where their distributions are Gaussian. When combining ACT with SPT, we use only ACT-E data to eliminate the covariance between ACT-S and SPT, which observe overlapping sky regions. We combine this likelihood with WMAP9, using the CosmoMC code [19] to estimate cosmological parameters.

We consider the basic spatially flat \(\Lambda\)CDM cosmological model defined by six parameters: the baryon and cold dark matter densities, \(\Omega_b h^2\) and \(\Omega_c h^2\); the angular scale of the acoustic horizon at decoupling, \(\theta_A\); the reionization optical depth, \(\tau\); the amplitude and the scalar spectral index of primordial adiabatic density perturbations, \(\Delta^2_s\) and \(n_s\) (at a pivot scale \(k_0 = 0.05\) Mpc\(^{-1}\)). We also extend the standard model to include a seventh parameter \(N_{\text{eff}}\), the effective number of relativistic species at decoupling. The high-\(\ell\) damping tail measured by ACT and SPT is particularly sensitive to this parameter.

### III. RESULTS AND DISCUSSION

The simple \(\Lambda\)CDM model fits all the data well, with the estimated parameters shown in Table I and Fig. 2. We find \(\chi^2 / \text{d.o.f.} = 37.9 / 42\) [probability to exceed (PTE) = 0.65] for ACT and 53.2/47 (PTE = 0.25) for SPT when combined individually with WMAP9, assuming the degrees of freedom equal the number of additional data points. The best-fitting parameters for ACT are all within about 1\(\sigma\) of the corresponding best-fitting parameters for SPT. For the combined analysis, the ACT + SPT best fit \(\chi^2 / \text{d.o.f.} = 78.9 / 68\) (PTE = 0.17). Compared to the joint best-fit model, the SPT-only best fit has \(\Delta \chi^2 = 2.5\) worse and the ACT-only best fit (for ACT-S+ACT-E) has \(\Delta \chi^2 = 2.2\), indicating that the common model fits both data sets. Figure 3 shows the residual power for the high-\(\ell\) data sets after subtracting the joint best-fitting model. We do not observe any particular features in ACT; the SPT power is more suppressed at multipoles \(\ell \gtrsim 1500\), but the points include an uncertain correlated extragalactic foreground contribution, whose dominant term is a Poisson shape.

The addition of ACT and SPT helps WMAP constrain the basic six parameters due to a more precise determination of the higher order acoustic peak positions and amplitudes. The measurement of \(\theta_A\) improves by a factor of 2.2 and the error on the baryon density is a factor of 1.6 smaller compared to WMAP9 alone. However, as noted in Ref. [11], the increased acoustic horizon scale leads to a predicted distance, \(D_V\), to objects at redshift \(z = 0.57\), in units of the sound horizon at recombination, \(r_s\), of \(100 r_s / D_V = 7.66 \pm 0.14\), more than 2\(\sigma\) larger than measured by the BOSS experiment ([20], 100 \(r_s / D_V = 7.3 \pm 0.1\)). The prediction at \(z = 0.35\), 100 \(r_s / D_V = 11.57 \pm 0.26\), is consistent at 1\(\sigma\) with the SDSS DR-7 observations ([21], 100 \(r_s / D_V = 11.3 \pm 0.2\)). We find a

The CMB power spectrum is sensitive to the composition
The radiation energy density is the energy density in photons plus the sum of the energy
density in relativistic species that do not couple electromagnetically, including standard model neutrinos. We
parametrize the energy density in other relativistic particles through \(N_{\text{eff}}\). In the standard cosmological model, \(N_{\text{eff}} = 3.046\) [22–24] describes the three known neutrino species. If there is an extra neutrino species that decouples at the
same temperature as the standard neutrinos then \(N_{\text{eff}} \approx 4\). If, instead, there is another light weakly interacting stable
particle that decouples earlier, it will increase \(N_{\text{eff}}\) by the
cube of the ratio of the decoupling temperatures. The extra
energy density in relativistic species has three noticeable
effects on the CMB power spectrum [25–28]: (1) it
increases the expansion rate of the Universe, which
impacts both the acoustic and damping scale, an effect
that is mostly degenerate with increasing the matter density, \(\Omega_{\text{m}} h^2\); (2) it modulates the helium abundance from big
bang nucleosynthesis, which in turn modifies the damping
tail through free electrons available at recombination; and
(3) the relativistic particles will free stream out of density fluctuations and suppress the amplitude of the power spectrum on small angular scales (an effect partially degenerate

\(^a\) The combination ACT + SPT uses ACT-E data only. We report errors at 68% confidence levels.

\(^b\) Derived parameters: Dark energy density, the amplitude of matter fluctuations on 8 h\(^{-1}\)Mpc scales, the age of the Universe in Gyr, the Hubble constant in units of km/s/Mpc, and the galaxy correlation scales at redshifts 0.57 and 0.35.

FIG. 2 (color online). Marginalized one-dimensional distributions for the six basic \(\Lambda\)CDM parameters, for combinations of WMAP9 (W9), ACT (A) and SPT (S) data.

FIG. 3 (color online). Residual power after subtracting the same best-fitting lensed CMB model. The reduced \(\chi^2/d.o.f\) for ACT is 40.1/42 (PTE = 0.55) and for SPT 55.7/47 (PTE = 0.18). We show ACT-E and ACT-S coadded residuals. The grey band in the bottom panel shows the 2\(\sigma\) uncertainty in the Poisson source component. Overall calibration errors are not included.
with increasing $n_s$, which enhances the amplitude of the power spectrum on those scales).

In our analysis, we vary $N_{\text{eff}}$ as a free parameter and we assume that the same relativistic species are present at nucleosynthesis. We keep other quantities that describe the damping tail set to standard values: the total available electron abundance (determined by the primordial helium abundance $Y_p$) is consistent with standard big bang nucleosynthesis; the higher precision determination of recombination is used [29], as implemented in Ref. [30]. Combining the data we are considering in this work we find at 68% confidence level

$$N_{\text{eff}} = 2.90 \pm 0.53 \quad \text{(WMAP9 + ACT)}$$
$$N_{\text{eff}} = 3.75 \pm 0.47 \quad \text{(WMAP9 + SPT)}$$
$$N_{\text{eff}} = 3.37 \pm 0.42 \quad \text{(WMAP9 + ACT + SPT)}.$$

In Fig. 4 we show the distribution for $N_{\text{eff}}$ from WMAP9 combined with ACT and SPT separately, and together. There is a 1.2$\sigma$ difference between the ACT and SPT estimates; as noted in Ref. [11], the SPT data prefer a higher value, indicating more suppression of the small-scale spectrum. The probability that this variation is given by statistical scatter is around 50% [31]. Based on the difference in the damping tail measurements, the authors of Ref. [33] decided not to combine the ACT and SPT data. In this paper we take a different approach and view the consistency sufficient for combination. As noted in Ref. [34], a Bayesian model comparison shows no evidence in favor of adding an additional $N_{\text{eff}}$ parameter beyond those of the standard cosmology.

The correlations among $N_{\text{eff}}$, $n_s$, and $H_0$ are also shown in Fig. 4; the suppression of small-scale power due to larger values of $N_{\text{eff}}$ can be partially compensated by increasing $n_s$ and $\Omega_m h^2$. This leads to a larger derived value of $H_0$ if the CMB peak positions are held fixed.

Since a higher value for $N_{\text{eff}}$ requires a higher matter density today, it gives a higher amplitude of gravitational potential fluctuations and an increased gravitational lensing signal. Measurements of the four-point function of the CMB temperature maps provide a measurement of the lensing deflection signal. The ACT [7] and SPT [14] data constrain the amplitude of the lensing potential power spectrum at $\ell = 400$ to be $C_{400}^{\kappa} = (3.69 \pm 0.80) \times 10^{-8}$ for ACT and $C_{400}^{\kappa} = (2.92 \pm 0.54) \times 10^{-8}$ for SPT, yielding a combined $C_{400}^{\kappa} = (3.17 \pm 0.45) \times 10^{-8}$. Adding this constraint gives

$$N_{\text{eff}} = 3.28 \pm 0.40$$

(WMAP9 + ACT + SPT + Lensing), consistent with three neutrino species.

IV. CONCLUSIONS

Current microwave background power spectrum measurements are consistent with the standard $\Lambda$CDM cosmological model, and independent data sets are consistent with each other, with a mild tension between the ACT and SPT damping tails. Upcoming maps from the Planck satellite will provide independent measurements of the same sky regions with excellent foreground characterization.

We acknowledge the use of the Legacy Archive for Microwave Background Data Analysis (LAMBDA). Support for LAMBDA is provided by the NASA Office of Space Science. The likelihood code will be made public through LAMBDA [36] and the ACT website [37].

[15] Here we use a slightly adapted binning of the spectra compared to those used in Refs. [8,9]; this is preferable as it gives the two ACT regions more similar bandpower window functions. Using the new binning alters cosmological parameters by $\lesssim 0.1 \sigma$. The lensing amplitude reduces by about 0.2$\sigma$. The new beam profiles described in [16] have a negligible ($\lesssim 0.2\sigma$) impact on the parameters, as discussed in more detail in [9].
[17] In the secondary model there are six common parameters: two for the thermal and kinematic SZ effects, three for the CIB clustered and Poisson power, and a cross correlation between tSZ and clustered CIB power. There is a separate Poisson radio power each for ACT and SPT; two Galactic parameters for ACT; and four calibration parameters for ACT, as described in Ref. [8].
[18] Using these SPT CMB-only bandpowers with the WMAP seven-year data we find the same cosmological parameters as in Ref. [10]. This indicates that the foreground priors imposed in the SPT team’s analysis (on the total SZ power, the clustered source power, and the Poisson source power) are consistent with the power that results from our multifrequency analysis. It also further validates this new approach of premarginalizing over the foregrounds.
[31] We perform an independent test of the degree of damping using the analysis of Farhang et al. [32], testing deviations from standard recombination history [29]. Reference [32] shows that two ionization fraction eigenmodes can be measured using WMAP7 + SPT and WMAP7 + ACT data. The most sensitive mode mainly measures changes in the overall damping scale parameter, defining the shape of the $C_{\ell}$ damping envelope. We measure unity normalized mode amplitudes of 0.14 $\pm$ 0.45 for WMAP9 + ACT, and $-0.80 \pm 0.37$ for WMAP9 + SPT, indicating a mild tension for SPT. The combined WMAP9 + ACT + SPT gives $-0.48 \pm 0.34$. The relative $C_{\ell}$ deviation from changing $Y_{p}$ looks similar to this dominant mode and has no tension with BBN, with $Y_{p} = 0.276 \pm 0.022$ for WMAP9 + ACT + SPT.
