Theoretical Analysis of AlAs$_{0.56}$Sb$_{0.44}$ Single Photon Avalanche Diodes with High Breakdown Probability

Jamal Ahmed, Shiyu Xie, Baolai Liang, Xin Yi, Xiao Jin, Manoj Kesaria, John. P. R. David, Fellow, IEEE, and Diana L. Huffaker, Fellow, IEEE

Abstract—Single photon avalanche diodes (SPADs) are key enabling technologies for a wide range of applications in the near-infrared wavelength range. Recently, AlAs$_{0.56}$Sb$_{0.44}$ (hereafter AlAsSb) lattice-matched to InP has been demonstrated for extremely low excess noise avalanche photodiodes (APDs) due to its large disparity between electron and hole ionization coefficients ($\alpha$ and $\beta$ respectively). The $\alpha/\beta$ ratio also plays a role in Geiger mode operation as it affects the avalanche breakdown probability and hence detection efficiency. In this work, we theoretically investigate the performance of AlAsSb based SPADs. The probability of breakdown for electron-initiated Geiger mode operation increases more sharply with multiplication region width due to progressively more dissimilar ionization coefficients. In comparison with other common avalanche materials, such as InAlAs, InP and Si, our result also suggests that SPADs based on AlAsSb have a sharper breakdown probability than the other three materials under similar low overbias ratio. The calculated breakdown probability of 0.81 in AlAsSb is 0.18 and 0.28 higher than that of InAlAs/Si and InP respectively at 5% overbias ratio and with avalanche region width of 1500 nm.

Index Terms— Avalanche Breakdown Probability, Single Photon Avalanche Diode.

I. INTRODUCTION

Single Photon avalanche diodes (SPADs) operating at near-infrared (NIR) wavelengths are of significant interest in several applications including quantum cryptography [1], CMOS circuit characterization [2] and eye-safe Light detection and ranging (Lidar) [3]. SPADs operate in the so-called Geiger mode biased above breakdown voltage $V_{BD}$ with an overbias ratio $(V-V_{BD})/V_{BD}$. This is a metastable state as a single carrier pair generation can cause the device to breakdown leading to a large current swing that can be easily detected by electronic circuitry.

SPADs are characterized by their single photon detection efficiency (SPDE) and dark count rate (DCR). The SPDE is the product of photon absorption efficiency and the probability of the generated electron-hole pair triggering an avalanche breakdown, termed the breakdown probability. The DCR mainly originates from tunneling dark currents through the avalanche region or traps triggering the avalanche breakdown. A large overbias ratio increases the SPDE but often at the expense of an increased DCR. It is well known that in linear mode Avalanche Photodiodes (APDs), a material with a large electron ($\alpha$) and hole ($\beta$) ionization coefficients ratio gives rise to a lower excess noise performance [4]. A larger $\alpha/\beta$ ratio is also desirable in SPADs for Geiger mode operation as it gives rise to a much steeper breakdown probability as a function of overbias ratio (for the electron-initiated process) [5]. However, the DCR also increases with the overbias due to the increased tunneling current generation. For instance, Itzer et al. [6] reported that their InP SPAD has almost 10 times increase in DCR (from 8 kHz to 75 kHz) when the overbias ratio increases from 7.5% to 15% to achieve desired SPDE (from 18% to 37%). This significant increase in DCR is attributed to the field-assisted tunneling current [6]. Thus, a large $\alpha/\beta$ ratio can improve SPAD performance considerably by operating at a relatively low overbias, thereby reducing DCR while still maintaining high SPDE.

Currently, NIR SPADs are based on a separate absorption and multiplication (SAM) heterostructure [7]. Typically, these devices utilize InP or In$_{0.52}$Al$_{0.48}$As (hereafter InAlAs) as avalanche multiplication region and In$_{0.53}$Ga$_{0.47}$As (hereafter InGaAs) as the absorption region. Alternatively, silicon (Si) based SPADs with germanium (Ge) absorber have also been demonstrated for NIR wavelength range [8]. Both InP and InAlAs have broadly similar $\alpha$ and $\beta$ and are thus not optimal for achieving high detection efficiency, whereas Si which exhibits a larger $\alpha/\beta$ ratio has a large lattice-mismatch with Ge making device fabrication challenging. Recently, a novel alternative avalanche material AlAs$_{0.56}$Sb$_{0.44}$ (hereafter AlAsSb) has been demonstrated to have a $\alpha/\beta$ ratio much larger than any other III-V semiconductor and even Si [9]. AlAsSb can be grown on InP substrate with a relatively large indirect bandgap of 1.55 eV and is thus compatible with...
existing InGaAs technology for 1310/1550 nm detection. However, at present, only linear mode APDs based on AlAsSb p-i-n structures have been reported [10]. An analysis of the Geiger performance of this material has yet to be investigated.

In this work, we investigate theoretically the performance advantages of AlAsSb based SPADs when compared to InP, InAlAs or Si.

II. MODEL DESCRIPTION AND VALIDATION

The device model is developed in commercial software, Silvaco Atlas [11]. Detailed modelled structure of AlAsSb p-i-n APD on InP substrate is shown in Table 1. The intrinsic region (w) ranging from 100 to 2000 nm is sandwiched between 300 nm p+ AlAsSb and 100 nm n+ AlAsSb cladding layers with top 20 nm and bottom 500 nm of InGaAs contact layers. The modelled structures are the same as reported in Ref. [9], [10], [12] and [13].

Our model includes a set of fundamental physics equations which have been derived from Maxwell’s laws and consist of Poisson’s equation, the continuity equations and transport equation. Poisson’s equation relates variations in the electrostatic potential to the local charge density. By solving the Poisson’s equation and hence fitting the device capacitance-voltage (C-V) results, we can extract the background doping concentration and the peak electric field in the device. For example, Fig. 1 (a) shows our fitted C-V result for AlAsSb APD with w = 1000 nm and the obtained background doping concentration for AlAsSb is 1x10¹⁵ cm⁻³. We also apply the continuity and the transport equations to describe the electron and hole densities as a result of the drift-diffusion transport process, SRH generation–recombination and photo-absorption process. The absorption coefficients of InGaAs [14] and AlAsSb [10] are incorporated in the model to determine the light intensity absorption profiles. We further calculate the device avalanche multiplication at high reverse bias by incorporating the local impact ionization theory in the model. Impact ionization coefficients for AlAsSb are used as input parameters taken from Yi et al. [9]. Our simulated results show that the avalanche multiplication values for pure electron injection (λ = 420 nm) agree well with the experimental data for AlAsSb APDs with w between 100 and 1500 nm, as shown in Fig. 1 (b). Here, for the well-known dead-space effect, enabled impact ionization coefficients are used for AlAsSb APD with w = 100 nm and the electron and hole threshold energy are extracted with the values of 3.0 and 3.8 eV, respectively.

Since our model has demonstrated good agreement with AlAsSb APD performance in linear mode, we further investigate the Geiger mode operation in AlAsSb SPAD with ideal p-i-n structures. The device probability of breakdown (Pᵇ) is calculated using line integrals of ionization rates along paths of the steepest potential gradient suggested by McIntyre [5]. Device breakdown voltage, V BD, is determined at Pᵇ ≈ 0.01. To validate our model, we carry out a comparison of the calculated Pᵇ at different overbias ratios with the reported data [15] for InP SPAD with w = 1 and 2 µm under pure hole injection. From Fig. 2, it is clear to see that our modelled results are in good agreement with the reported values. The inset of Fig. 2 includes the calculated Pᵇ at different reverse bias. Similar good agreement was also achieved for Si [16] and InAlAs [17] SPADs using our model. The carrier impact ionization rates of InP, InAlAs and Si are taken from Ref. [18], [19] and [20] respectively.

III. COMPARISON OF Pᵇ IN DIFFERENT SPADS

Having validated our model, AlAsSb p-i-n SPADs with w

![Graph of measured and modelled C-V for AlAsSb p-i-n diode with w = 1000 nm](image1)

![Graph of measured and modelled gain for AlAsSb p-i-n diode with different w](image2)
Fig. 2. Comparison of pure hole-initiated $P_b$ for InP p-i-n diode with $w = 1$ μm and 2 μm calculated from our model (solid lines) and taken from Ref. [15] (symbols). Inset shows the corresponding calculated $P_b$ vs. reverse bias.

Fig 3 (b) shows the calculated $P_b$ as a function of overbias ratio for AlAsSb SPADs. The $P_b$ curves rise more abruptly for $w \geq 1000$ nm at overbias ratio ≤ 8%; however, the $P_b$ increment is much slower with $w \leq 500$ nm, especially for that with $w = 100$ nm. For example, at 5% overbias ratio, AlAsSb SPAD with $w = 1500$ nm shows a $P_b$ value of 0.81, which is significantly higher than that of 0.33 with $w = 100$ nm. Hence, AlAsSb SPADs with thicker $w$ shows an advantage of higher $P_b$ values. However, it is worth noting that a further increase of the overbias ratio above 8% does not yield substantial performance improvement for AlAsSb SPADs with $w \geq 1000$ nm as their $P_b$ curves start to saturate.

The sharper $P_b$ curves of thicker AlAsSb SPADs can be explained by analyzing the operating fields and corresponding $\alpha/\beta$ ratio for an overbias ratio of 5% as shown in Fig. 4. The operating field is ~1.07 MV/cm for a device with $w = 100$ nm while it is approximately half of the field value (~0.56 kV/cm) for $w = 2000$ nm. This leads to a significant increase of $\alpha/\beta$ ratio from ~3.9 to ~28.9, and thus results in a higher $P_b$ value [5]. In addition, the lower operating fields in the thicker structure may have an additional advantage of lower tunneling currents and, thus, lower DCR. For devices beyond $w = 1500$ nm (corresponding to operating field ≤ 590 kV/cm), the $\alpha/\beta$ ratio does not increase significantly leading to only a minor improvement in $P_b$ values ($\alpha/\beta$ ratio of ~22.3 and ~28.9 for $w = 1500$ and 2000 nm, respectively). Considering AlAsSb SPAD operation with high $P_b$ (high SPDE) at low over bias ratio (low DCR) and the growth difficulty for thicker $w$ because of the non-unity sticking coefficient of group V species (As, Sb) [24], we deem the operating thickness for AlAsSb SPAD to be $w$ between 1000 and 1500 nm.

Finally, we compare $P_b$ values of AlAsSb SPAD with Si, InP and InAlAs SPAD at different overbias ratio. Fig. 5 (a) shows the calculated results for $w = 1500$ nm. Among the four types of SPADs, AlAsSb exhibits the sharpest rise in $P_b$ curve. At an overbias of 5%, the calculated $P_b$ value is 0.81, which is 0.18 and 0.28 higher than that for Si/InAlAs and InP respectively. To achieve $P_b = 0.81$ in InP, the overbias ratio of ~11% is necessary and the peak electric field increases from ~439 kV/cm to 463 kV/cm. This results in an order of magnitude increase of band-to-band tunneling current [26]. Donnelly et al. [27] reported that DCR of dummy InP SPADs (with $w = 1400$ nm and 1500 nm absorber) increases almost 10 times when the overbias voltage is increased from 4V to 10V corresponding to a $P_b$ of ~0.51 and ~0.82 respectively. Since AlAsSb has a higher breakdown voltage than the rest of three materials, we also compare $P_b$ for an alternative case at a fixed $V_{BD}$. Fig. 5 (b) shows an example of our calculated $P_b$ at a fixed $V_{BD} = 60$ V (for AlAsSb SPAD with $w = 1000$ nm). AlAsSb still exhibits the highest $P_b$ with a value of 0.74 at 5% overbias while it is 0.53 for InP.

The $\alpha/\beta$ ratios of the four devices at 5% overbias for $w$...
Fig. 4. Operating electric field and the corresponding $\alpha/\beta$ ratio vs. $w$ at 5% overbias ratio.

$w = 1500$ nm and $V_{BD} \approx 60$ V are also shown in Fig. 5 (c). We can observe that AlAsSb has the largest $\alpha/\beta$ ratio among the four materials for both cases. There is an overall trend that a larger $\alpha/\beta$ ratio leads to a larger $P_b$ value (hence higher SPDE), which is consistent with Ref. [5]. However, there is an exceptional case that, at $w = 1500$ nm, Si and InAlAs show similar $P_b$ values while Si has a larger $\alpha/\beta$ ratio (value of 4.6) than that of InAlAs ($\alpha/\beta$ ratio of 3). Comparison of ionization coefficients of the four materials for their respective operating fields under consideration shows that InAlAs has more sharply increasing $\alpha$ and $\beta$ than that of Si as shown in Fig. 5(d). This could explain a similar $P_b$ value as Si at $w = 1500$ nm [28].

In Fig. 5 (d), we can notice that AlAsSb operates at higher fields than the other three materials, but its higher indirect bandgap (~1.55 eV) results in a significantly lower band-to-band tunneling current [29] than both InAlAs and InP. For instance, no measurable band-to-band tunneling current was reported in AlAsSb APD at electric field up to 1.07 MV/cm [29], but the tunneling current density of $\sim 10^{-3}$ and $\sim 10^{-4}$ A/cm$^2$ were reported for InAlAs [19] and InP [26] respectively at field of 800 kV/cm. Hence, it is unlikely that the band-to-band tunneling mechanisms will dominate DCR in AlAsSb SPAD at the operating field up to ~800 kV/cm as shown in Fig. 5 (d). Fig. 6 shows an example of the measured dark current density ($J_D$) vs. the calculated peak electric field for $0.9 V_{in}$ for AlAsSb devices with $w = 1000$ nm (up to 600 kV/cm) and $w = 1500$ nm (up to 565 kV/cm) at 297 K and 77 K. The expected dark current ($I_D$) for a 25 $\mu$m diameter device is also indicated on the right y-axis, which is a typical size for III-V SPADs found in literature [30]. The measured $J_D$ for both devices reduces by approximately 2-4 orders of magnitude when the operating temperature drops from 297 K to 77 K, suggesting that the devices are dominated by the surface leakage current instead of band-to-band tunneling.
current. Our current devices with \( w = 1500 \text{ nm} \) show a high \( J_0 \) of \( 7 \times 10^6 \text{ A/cm}^2 \) at 77 K; however, devices with \( w = 1000 \text{ nm} \) demonstrate \( J_0 \leq 6 \times 10^3 \text{ A/cm}^2 \) that corresponds to \( I_0 = 3 \text{ pA} \) at 77 K for a 25 \( \mu \text{m} \) diameter device at 0.9\( V_{\text{BD}} \). The higher dark current in our current AlAsSb devices with \( w = 1500 \text{ nm} \) may be due to the higher density of defects inside the multiplication layer and this variation was due to the different growth trials/time for different layer thickness. Nevertheless, further improvement of the as-grown material quality by reducing its defect density, and optimization of device processing such as improving etching and passivation recipe or utilizing planar structures to minimize the device leakage current, are necessary to achieve a low DCR SPAD with low afterpulsing. Together with the high \( P_0 \) in AlAsSb, there is a potential for AlAsSb SPADs with high SPDE/DCR ratio at low overbias assuming similar generation mechanisms as observed in InP SPAD [6].

Temporal response is another important parameter to evaluate SPAD performance, however, it has not been included in this work yet as this functionality/module is not included in our Silvaco software. The timing jitter (the standard deviation of the mean time to breakdown) in SPAD deteriorates with larger \( \alpha/\beta \) ratio but it improves with \( P_0 \) [31]. Hence at similar low overbias ratio of \( \leq 5\% \), we expect the timing jitter of AlAsSb SPAD can be comparable to InP SPAD for its much higher \( P_0 \).

IV. CONCLUSION

In this work, we presented a model for AlAsSb APD/SPADs. Comparison of experimental and modelling data for multiplication gain in AlAsSb APD shows excellent agreement at different multiplication region thicknesses. Model validation also includes the calculated \( P_0 \) compared with the reported data for InP/InAlAs/Si SPADs. We demonstrate that AlAsSb SPAD, at both \( w \) of 1500 nm and a fixed \( V_{\text{BD}} \) value of 60V, shows higher \( P_0 \) values compared with Si, InAlAs and InP SPAD. This indicates a potential of higher SPDE/DCR ratio for AlAsSb SPAD at low overbias ratio of \( \leq 5\% \) if it is dominated by similar field-assisted tunneling current mechanisms as InAlAs and InP SPADs. However, further material quality control during epitaxy and device fabrication optimization and/or planar structures are still necessary for the operation of AlAsSb based SPAD. Our results suggest the high potential of utilizing AlAsSb as avalanche gain medium for SPAD applications.
