The temperature dependence of magnetization, magnetic anisotropy, and coercive field of gallium-substituted cobalt ferrite was investigated for a series of compositions of CoGa$_x$Fe$_{2-x}$O$_4$ ($0 \leq x \leq 0.8$). Hysteresis loops were measured for each sample over the range of $-5 \, \text{T} \leq \mu_0H \leq 5 \, \text{T}$ for selected temperatures between 10 and 400 K. The magnetization at 5 T and low temperatures was found to increase for the lower Ga contents ($x=0.2$ and 0.4) compared to pure CoFe$_2$O$_4$, indicating that at least initially, Ga$^{3+}$ substitutes predominantly into the tetrahedral sites of the spinel structure. The high field regions of these loops were modeled using the law of approach to saturation, which represents the rotational process, together with an additional linear forced magnetization term. The first order cubic magnetoelastic anisotropy coefficient $K_1$ was calculated from curve fitting to these data. It was found that $K_1$ decreased with increasing Ga content at all temperatures. Both anisotropy and coercivity increased substantially as temperature decreased. Below 150 K, for certain compositions ($x=0$, 0.2, 0.4), the maximum applied field of $\mu_0H=5 \, \text{T}$ was less than the anisotropy field and, therefore, insufficient to saturate the magnetization. In these cases, the use of the law of approach method can lead to calculated values of $K_1$ which are lower than the correct value. © 2008 American Institute of Physics. [DOI: 10.1063/1.2832503]

**INTRODUCTION**

There has been much interest recently in the properties of magnetoelastic cobalt ferrite and cobalt ferrite composites.1–4 These materials exhibit high levels of magnetostriiction $\lambda$ and high sensitivity to field $d\lambda/dH$, which make them candidate materials for stress and torque sensor, and actuator applications. Substitution of a cation $M$ for Fe in Co$_M$Fe$_{2-M}$O$_4$ reduces the Curie temperature and improves magnetic and magnetoelastic properties in the cases of $M=$Mn or Cr.3,4 To fully control the magnetomechanical response of these materials, more needs to be known about their magnetic properties and their temperature dependences, especially the magnetic anisotropy. In the present work, the effect of gallium substitution on the temperature dependence of magnetization, magneto crystalline anisotropy, and coercivity of CoGa$_x$Fe$_{2-x}$O$_4$ ($0 \leq x \leq 0.8$) was investigated over the temperature range of 10–400 K.

**EXPERIMENT AND RESULTS**

A series of gallium-substituted cobalt ferrite samples was prepared by standard ceramic techniques1,2 with a final sintering at a temperature of 1350 °C for 24 h, followed by furnace cooling to room temperature. Energy dispersive x-ray spectroscopy (EDS) was used to determine the actual final compositions of the samples, which were found to be close to the target compositions. Table I shows the comparison of target and actual compositions.

Dependence of technical saturation magnetization on temperature was measured using a superconducting quantum interference device (SQUID) magnetometer under an applied field of 5 T, as shown in Fig. 1. It was observed that magnetization monotonically increased as temperature decreased from 400 to 160 K for all samples. Below 160 K, magnetization increased slowly with decreasing temperature for most samples but decreased for pure CoFe$_2$O$_4$ (from 160 K) and CoGa$_{0.8}$Fe$_{1.2}$O$_4$ (from 100 K). This apparent decrease can be explained by the presence of high anisotropy fields at low temperatures for these samples, which prevented complete saturation of magnetization under the field strengths used.

Symmetric magnetic hysteresis loops were measured over temperatures ranging from 10 to 400 K using a SQUID magnetometer, with a maximum applied field of 5 T. An example of the temperature dependence of the first quadrant of the hysteresis curves is given in Fig. 2 for CoGa$_{0.6}$Fe$_{1.4}$O$_4$. The coercive fields for each sample at different temperatures are shown in Fig. 3.

For the calculation of anisotropy, it was assumed that

after the closing of the hysteresis loops, all the irreversible processes were finished. The high field regions represent the processes of rotation against anisotropy and at the higher temperatures, forced magnetization. According to the law of approach \(/
\) to saturation, the effect of these processes on magnetization, for \(H_{C}\), can be modeled by the equation

\[
M = M_s \left(1 - \frac{8}{105} K_1^0 \frac{1}{H^2} \right) + \kappa H, \tag{1}
\]

where \(M\) is magnetization, \(M_s\) is saturation magnetization, \(K_1\) is first order cubic anisotropy coefficient, \(H\) is magnetic field, and \(\kappa\) is the forced magnetization coefficient representing the linear increase in spontaneous magnetization at high applied field values. The constant \(8/105\) applies to first order cubic anisotropy of random polycrystalline samples.

The data from high field regimes were fitted to Eq. (1). To extract the most appropriate values of \(K_1\), \(M_s\), and \(\kappa\), only data at applied fields above 1 T were used to fit to the LA for temperatures above 150 K. For temperatures below 150 K, only data at applied fields higher than 2.5 T were fitted to the LA. The values of anisotropy coefficient \(K_1\) computed using this procedure are shown in Fig. 4. For low Ga content \((x = 0.0, 0.2, 0.4)\) and low temperatures \((T = 100, 50, 10)\ K\), it was observed that the value of kappa, calculated directly from the fits, increased with decreasing temperature, which is an artefact. In these cases, the estimated anisotropy fields were greater than the maximum applied field, thus indicating that anisotropy dominated over forced magnetization (see Conclusion and Refs. 3 and 4). Forced magnetization was assumed to be negligible at these temperatures and the experimental data were refitted to the LA with \(\kappa = 0\) for these points so that \(M_s\) and \(K_1\) were the only fitting parameters for these calculations. These points are connected with a dotted line in Fig. 4. The values of \(M_s\) obtained by fitting the experimental data to Eq. (1) were in agreement with the magnetization measured at an applied field of 5 T, except for the samples with \(x \leq 0.2\) for temperatures below 150 K. In these cases, the values obtained from the calculations were slightly above the measured values, which is consistent with the idea that the anisotropy field is greater than the maximum applied field.

**DISCUSSION**

Starting from 400 K, the anisotropy coefficient \(K_1\) is observed to increase with decreasing temperature for all compositions, with the region of steepest increase coming at progressively lower temperatures for increasing Ga content until \(x = 0.6\), then the \(x = 0.8\) sample was essentially the same as the \(x = 0.6\) sample. However, for the low Ga contents \((x = 0.0, 0.2,\) or 0.4) and lower temperatures, \(K_1\) calculated from the LA fits was observed to peak and decrease or level off. This
apparent decrease was because the anisotropy fields of these samples reach such high levels at low temperatures that the applied fields of up to $\mu_0 H = 5$ T (maximum available) were unable to saturate the magnetization.

Estimation of the anisotropy fields for these samples supports this idea. For a cubic crystal with the (100) easy directions such as cobalt ferrite, $H_K = 2K_1 / \mu_0 M_s$. The anisotropy field for pure cobalt ferrite at 150 K was estimated to be 4.8 T, and it should increase further at lower temperatures. Similarly, the estimated anisotropy field for the specimen with $x = 0.2$ at 100 K was 5.16 T. These ideas are also supported by the magnetization data for low Ga contents and low temperatures. For example, for pure cobalt ferrite ($x = 0$), magnetization has a maximum at 160 K for pure cobalt ferrite and for the gallium-substituted sample with $x = 0.2$, magnetization has a maximum at 100 K (see Fig. 1). Therefore, the anisotropy prevents a complete approach to saturation in these cases and, hence, the values of $K_1$ calculated from fitting the experimental data to the LA equation are unreliable.

The LA gives the absolute value of the cubic anisotropy coefficient $K_1$. To second order, the numerical expression is the same for cubic anisotropy with the (100) and (111) easy axes. Pure cobalt ferrite has been reported to have the (100) easy axis directions, with $K_1$ values that are positive and range from $2.1 \times 10^6$ to $3.9 \times 10^5$ J/m$^3$ at 300 K, with variation caused by heat treatment and stoichiometry of the material. The value of $K_1$ for pure cobalt ferrite at 300 K, in the present study, is $2.66 \times 10^5$ J/m$^3$. This is consistent with the results of Shenker, who measured anisotropy for single-crystal pure cobalt ferrite and also with the theoretical work of Tachiki for pure cobalt ferrite (see Fig. 4).

Despite the fact that the 5 T applied field cannot entirely saturate the lower Ga-content samples at the lower temperatures, magnetization at 10 K is clearly observed to increase for $x = 0.2$ and $x = 0.4$ samples compared to pure CoFe$_2$O$_4$ (see Fig. 1). This indicates that initially, at least, the Ga$^{3+}$ ions substitute into the tetrahedral sites in the inverse spinel structure. Ga$^{3+}$ has ten 3$d$ electrons and, thus, no magnetic moment. The net moment of ferrimagnetic spinels is determined by the difference of the octahedral moments $M_B$ minus the tetrahedral moments $M_A$. Thus, the only way that substituting nonmagnetic ions can make the magnetization increase, is if they substitute onto the tetrahedral sites. It is not clear why the low temperature magnetization decreases for the higher Ga contents ($x = 0.6$ and 0.8). It could be due to the additional Ga substituting into the octahedral sites for these compositions, or to noncollinear spin arrangements brought on by the decreased tetrahedral-octahedral exchange coupling. This will require further investigation.

The assertion that for low concentrations, Ga$^{3+}$ ions occupy tetrahedral sites, is further supported by recent Mössbauer spectroscopy data, which indicate that Ga$^{3+}$ ions appear to favor the tetrahedral sites in CoGa$_{x}$Fe$_{2-x}$O$_4$. Mn$^{3+}$ and Cr$^{3+}$, on the other hand, substitute into the octahedral sites and displace some of the Co$^{2+}$ onto the tetrahedral sites. According to the one-ion anisotropy model, the high anisotropy of cobalt ferrite is primarily due to the presence of Co$^{3+}$ ions on the octahedral sites of the spinel structure (see, for example, Ref. 5). For low concentrations of Ga$^{3+}$ ($x = 0.2$ and 0.4), although Ga$^{3+}$ ions go into tetrahedral sites, they still reduce the anisotropy. This is thought to be due to the reduction of the tetrahedral-octahedral exchange coupling. For the samples $x = 0.6$ and 0.8, however, the $K_1$ reduction could be caused by either of two mechanisms. Anisotropy could either decrease due to the additional Ga substituting into the octahedral sites for these compositions (and displacing Co$^{2+}$ ions to tetrahedral sites), or to further decrease of the tetrahedral-octahedral exchange coupling, which brings on noncollinear spin arrangements.

**CONCLUSION**

The effect of Ga substitution on the temperature dependence of the magnetic anisotropy, magnetization, and coercivity of polycrystalline cobalt ferrite CoGa$_{x}$Fe$_{2-x}$O$_4$ ($0 \leq x \leq 0.8$) was investigated over the temperature range of 10–400 K. The first order cubic anisotropy coefficient $K_1$ was estimated by fitting the high field region of the hysteresis loops to the law of approach to saturation. It was found that anisotropy of all Ga-substituted cobalt ferrite samples increased with decreasing temperature. It was also found that the anisotropy of gallium-substituted cobalt ferrite decreased with increasing gallium content at all temperatures. It was observed that the magnetization at 10 K increased for lower Ga contents ($x = 0.2$ and 0.4) compared to pure cobalt ferrite. The results indicate that Ga ions preferentially substitute into the tetrahedral sites. It was concluded that the anisotropy of CoGa$_{x}$Fe$_{2-x}$O$_4$ for low Ga content ($x = 0$, 0.2, and 0.4) was so high at low temperatures that it prevented complete approach to saturation, similar to what had been observed with Mn or Cr substitution. Thus, it is not possible to reliably calculate the values of $K_1$ at these low temperatures using the law of approach method.
