### Abstract

Mass dimensions of natural resources, established from power law scaling relationships between numbers of resources and distance from an origin, have important implications for ore-forming processes, resource estimation and exploration. The relation between the total quantity of resource and distance, measured by the mass-radius scaling exponent, may be even more useful. Lode gold deposits, geothermal wells and volcanoes, and conventional and unconventional gas wells are examined in this study. The scaling exponents generally increase from the lode gold through geothermal wells to gas data sets, reflecting decreasing degrees of clustering. Mass dimensions are similar to the mass-radius scaling exponents, and could be used as substitutes in the common case that data are not available for the latter. All of these resources are formed by fluid fluxes in the crust, and therefore percolation theory is an appropriate unifying framework to understand their significance. The mass dimensions indicate that none of the percolation networks that formed the deposits reached the percolation threshold.

Abbreviated title: Scaling laws for natural resource distribution
Abstract

Mass dimensions of natural resources, established from power law scaling relationships between numbers of resources and distance from an origin, have important implications for ore-forming processes, resource estimation and exploration. The relation between the total quantity of resource and distance, measured by the mass-radius scaling exponent, may be even more useful. Lode gold deposits, geothermal wells and volcanoes, and conventional and unconventional gas wells are examined in this study. The scaling exponents generally increase from the lode gold through geothermal wells to gas data sets, reflecting decreasing degrees of clustering. Mass dimensions are similar to the mass-radius scaling exponents, and could be used as substitutes in the common case that data are not available for the latter. All of these resources are formed by fluid fluxes in the crust, and therefore percolation theory is an appropriate unifying framework to understand their significance. The mass dimensions indicate that none of the percolation networks that formed the deposits reached the percolation threshold.

Key words. Mass dimension; fractal; resource; gold; percolation; unconventional gas resource

1. Introduction

Scaling laws have been applied to many aspects of natural resources. Mandelbrot (1983) suggested that mineral distribution in the Earth might be a fractal dust, and this idea has been followed up for hydrothermal mineral deposits (e.g. Carlson 1991; Blenkinsop 1994, 1995; Raines, 2008; Carranza 2009) and petroleum deposits (Barton and Scholz 1995). Fractal relations between ore grade and tonnage were described by Turcotte (1986), and fractal aspects
of structures in vein-hosted deposits have been described by Sanderson et al. (1994), Roberts et al. (1999), Johnston and McCaffrey (1996) and Nortje et al. (2006) among others. Fractal applications of geochemistry to natural resources have been well documented (e.g. Agterberg 1995; Agterberg et al. 1996; Cheng et al. 1994; Cheng 1999a, b, c, d). Describing the distribution of natural resources is useful in order to estimate total resources (e.g. Barton and Scholz 1995), and also has important implications for exploration strategies (e.g. Ford and Blenkinsop 2008), and for processes by which natural resources form (e.g. Arias et al. 2011).

The box counting method has been widely applied to quantify the distribution of natural resources, for example mineral deposits:

\[ N(\delta) \sim \delta^{Db} \]

Where \( N(\delta) \) is the number of boxes of side \( \delta \) required to cover the deposits. \( Db \) is the box-counting dimension, which is a measure of clustering (e.g. Carlson 1991). Uniform or random distributions have \( Db = 2 \); increasing degrees of clustering have smaller values of \( Db \). A more useful description of resource distribution may be given by the relation:

\[ M(r) \sim r^{Dm} \]

where \( M(r) \) is the mass of resource within a circle of radius \( r \) (e.g. La Pointe, 1995). If the mass of each resource occurrence is unity, this law describes the mass dimension \( Dm \) of the resource. \( Dm \) is also simply interpreted as a measure of the clustering of the resource distribution. The mass-radius relationship is sometimes expressed as the radial density function:
\[ d(r) \sim r^{D_{mr} - 2} \]

where \( d(r) = M(r)/\pi r^2 \) is the density of deposits as a function of \( r \) (e.g. Raines 2008).

However, the mass of resources typically varies at each location. This can be quantified by a general scaling law:

\[ M(r) \sim r^{-D_{mr}} \]

\( D_{mr} \) is referred to here as the mass-radius scaling exponent. This exponent can have values greater than 2, and is potentially a more complete description of the distribution of natural resources because it measures variations in mass of resource at each locality.

Mass dimensions have been investigated in diverse research fields, including astrophysics (e.g. Duval et al. 2010), neurobiology (e.g. Caserta et al. 1995), particle science (Liao et al. 2005), and texture analysis (e.g. Backes and Bruno 2013), but they have not been widely applied to natural resources. Box counting and mass dimensions have been determined for gold deposits (e.g. Carlson 1991; Blenkinsop 1994, 1995, Carranza 2009; Carranza et al. 2009; Carranza 2010; Carranza and Saghedi 2010) and for petroleum deposits (Barton and Scholz 1995), but mass-radius scaling exponents are hardly reported in the literature. The aim of this paper is to investigate mass dimensions and the suitability of the mass-radius scaling exponent to describe the distribution of some natural resources. Hydrothermal gold deposits, geothermal wells and volcanic vents, and gas wells are considered in this study. Each of the data sets represents the product of fluid flow systems in the crust; hence the relevance of percolation theory to the results is also considered.
2. Data and Methods

Mass dimensions and mass-radius scaling exponents have been determined in this study for Archean gold deposits in Zimbabwe (Figs. 1, 2), divided into a data set for the whole craton and a more detailed data set from the Masvingo area. Geothermal wells and volcanoes in Oregon (Fig. 3), and conventional and unconventional gas production in Pennsylvania (Figs. 4, 5, 6) were also analysed. Details of the data and sources are given in Table 1. In the Pennsylvania data, unconventional wells are considered as those drilled “for the purpose of or to be used for the production of natural gas from an unconventional formation” (https://www.paoilandgasreporting.state.pa.us/publicreports/Modules/DataExports/DataExports.aspx). All conventional wells are vertical, but most unconventional wells are horizontal. Virtually all unconventional wells, and by far the majority of conventional wells, produced gas only; there was some oil production from a few conventional wells.

Figs 1 – 6 here

Expanding circles used to count mass around a point were entirely constrained within the study area limits to avoid edge effects, and “mass” was normalized to the total value of the data sets \( \Sigma M \), so that \( M'(r) = M(r)/\Sigma M \). Two strategies were investigated for determining the exponents of the scaling laws:

1) A grid origin method, in which the mass was summed and averaged from expanding circles centred on 100 origins on grid nodes in the central part of the study area (cf. La Pointe 1995).

2) A data point origin method, in which counting circles were centred on data points, and average values were taken from every circle used.
Both methods were applied to the coordinates of the Koch curve as well as to all data sets. The grid origin method produced exponents with values that were all near 2, including for the Koch curve, and showed little variation between data sets. By contrast, the data point origin method returned a value of 1.26 for the Koch curve (the curve has a fractal dimension of 1.26; e.g. Peitgen et al. 2004), and discriminated sensitively between the data sets. Hence it was used for all results shown in this study.

Mass dimensions could be calculated for all data sets, and mass-radius scaling exponents could be calculated for gold production from the Zimbabwe craton and gas production from Pennsylvania, because these data sets included resource figures. Exponents were obtained by regression of log $M'(r)$ against log $r$ over the linear part of the scaling relationship, for a range of $r$ of 1 to 1.5 orders of magnitude. Lower and upper limits of regression are shown in Table 1.

3. Results

Linear parts of all data sets can be defined over at least an order of magnitude (Figs. 7 - 10), justifying the above regression technique. The data sets showed two characteristic features. At both low and high values of $r$, the slopes of the log mass-radius relations were less than the central part of the data, where the regression was carried out (e.g. Fig. 7). Mass dimensions vary between 1.2 and 1.8 (Table 2). Standard errors of regression vary from 0.009 to 0.017, indicating that the range of mass dimensions measured shows significantly different degrees of clustering between different data sets.

Figs. 7 – 10 here

The gold deposits of the Zimbabwe craton have the lowest mass dimensions of all data sets
considered, indicating the greatest degrees of clustering (Table 2). The mass-radius scaling exponent is within regression error of the mass dimension for the cratonic data set. The mass dimension for the Masvingo data set is significantly greater than for the craton data.

The geothermal wells of Oregon have a stepped log mass-radius relation (Fig. 8) in which two segments of similar slope are offset from one another. The mass dimension of the larger part of the data is 1.23 (Table 2). The volcanic vents of Oregon have a mass dimension of 1.51 (Fig. 8).

Unconventional gas wells in Pennsylvania have mass dimensions of 1.26 (producing wells) and 1.45 (all wells) (Table 2). The mass-radius scaling exponent of the producing wells, 1.32, lies between these values. The highest values of mass dimension are from conventional gas production, (1.57 and 1.63 for all wells and producing wells respectively). The mass-radius exponent of the producing wells is the highest value measured, 1.72.

4. Discussion

4.1 Consistency with previous results

Mass dimensions of various types of gold deposit have been presented by Blenkinsop (1994, 1995), Carranza (2009; 2010) and Carranza et al. (2009). In all these studies, different fractal dimensions are given at low and high r values, ranging from 0.54 for the low r values, to 1.52 (high r). Mass-radius scaling exponents were calculated for nine hydrocarbon plays by La Pointe (1995) using area of hydrocarbon fields as a measure of mass, and reported as between 1 and 2. The mass dimensions and mass-radius scaling exponent reported here are therefore broadly consistent with the few previous results reported in the literature from similar commodities.
4.2 Non-linearity of logarithmic mass-radius scaling

The log mass-radius scaling relations examined are characteristically non-linear at values of $r$ generally less than 1000 m, illustrated for the Masvingo data set in Fig. 7, but also seen at lower values of $r$ than shown in the other data sets. This non-linearity is similar to the “roll-off” observed in box-counting plots at low $\delta$ values (e.g. Pickering et al. 1995). For gold deposits of the Zimbabwe craton, this effect has been attributed to random sampling of a fractal data set (Blenkinsop and Sanderson 1999), and it seems likely that the same explanation applies here, i.e. that the actual data sets represent samples of a true fractal distribution. The log mass-radius relations show less mass at high values of $r$ than predicted by a linear relation. It is noticeable that the non-linearity occurs at radii that are about $¼$ of the maximum linear dimension of the study areas or greater. Counting circles with these large $r$ values are only taken from the centre of the study areas: thus, concentrations of resources near the corners will not be included, possibly leading to a deficit, in the case of clustering near the peripheries of the study areas.

4.3 Mass dimensions of data sets vs. natural resources

True mass dimensions of natural resources should reflect resource-forming process. For hydrothermal mineral deposits and hydrocarbons, this may include elements of source distribution, fluid transport and deposition (trapping mechanisms). However, mass dimensions estimated from resource databases such as those used here will be influenced by the degree of exploration and other economic factors. The extent to which the Zimbabwe data are affected by this is discussed in Blenkinsop and Sanderson (1999), but how well the other data sets used here reflect the actual distribution of resources in the Earth is unknown. The production of gas from horizontal drilling (e.g. Arthur et al. 2008) could affect the distribution of wells on a hundred m scale.
Despite the possible influence of non-geological factors, the results reported here make geological sense. Hydrothermal mineral deposits such as gold are strongly structurally controlled by specific deformation zones (e.g. Groves et al. 1998; Wit and Vanderhor 1998; Cox 1999). This leads to strong clustering of gold deposits (Blenkinsop 1994, 1995, Caranza 2009). Hydrocarbon resources, including gas, are also structurally controlled: the influence of structure in the Marcellus Shale can clearly be seen at a small scale (Fig. 6). Source and trap rock types and burial history are also very important, and the generally low values of mass dimensions for the gas resources of Pennsylvania reflect the presence of the Marcellus Shale under most of the state. Shale gas is formed and trapped in situ in shales, so that the host rock is both source and reservoir, and thus potentially making large parts of the Marcellus shale that have had the correct burial history into unconventional gas sources (Kargbo et al. 2010), and giving a less clustered distribution than the gold deposits.

The distribution of geothermal wells is related to geothermal structure, which is a function of tectonics. The tectonics of Oregon are dominated by the Cascadia subduction zone, which creates the Cascade volcanic arc and determines the location of volcanoes (Priest 1990). Heat flow is thought to be influenced by the presence of partial melts in the mid crust at depths of 10 km (Blackwell et al. 1990). However, on a more local scale in North-Central Oregon, regional groundwater flow modifies the conductive flux by sweeping heat from young elevated rocks into adjacent older rocks at lower elevations (Ingebritsen et al. 1989; Blackwell et al. 1990).

4.4 Percolation theory: a unifying framework

The formation of all the georesources considered above is linked by fluid flow. A possible unifying framework for considering the mass dimensions and mass-radius scaling exponents is therefore percolation theory. This concept has been applied to the formation of hydrothermal gold
deposits (Cox 1999) in the context of fluid flow in fracture networks (e.g. Rivier et al. 1985), and there is an extensive literature on applications of percolation theory to primary migration of hydrocarbons (e.g. Carruthers and Ringrose 1998; Carruthers 2003; Corradi et al. 2009). General aspects of percolation theory may therefore assist with interpretation of the results presented here (cf. Cox 1999).

A percolation network consists of a lattice in which some sites are occupied, with a probability $p$ of occupation (Stauffer and Aharony 1994). As the network evolves, $p$ changes. Many aspects of percolation networks are fractal, for example the dimensions and numbers of clusters of occupied sites, and times for their evolution. As $p$ increases, a critical stage is reached called the percolation threshold, defined as the point at which a continuous path of occupied nodes exists from one side of the network to the other, and the network changes from closed to open. The percolation threshold occurs at a critical probability $p_c$. Fractal dimensions of percolation networks change over a considerable range as $p$ increases, but can be simplified into three conditions: $p < p_c$, $p = p_c$ and $p > p_c$. Two and three dimensional mass dimensions for percolation networks consisting of a Bethe lattice (in which every site has the same number of neighbours and there are no closed loops) in these three stages are shown in Table 3.

The study areas of the Zimbabwe craton, Oregon, and Pennsylvania, have linear dimensions of hundreds of km compared to crustal thicknesses of tens of km (Nelson, 1992; Nguuri et al. 2000; Eagar et al. 2011). It may therefore be reasonable to compare the mass dimensions of this study to those of 2D percolation networks. All the mass dimensions measured here are below the mass dimensions of 2D Bethe lattices at the percolation threshold. In the case of gold deposits, this is intuitively reasonable. Once a backbone, network-spanning cluster has formed in a hydrothermal system, the localization of fluid flow along this structure would preclude mineralization
elsewhere. Mass dimensions of the gas wells are closer to the 2D threshold value, which may be
reflected in their more distributed pattern (Fig. 9). It is also reasonable that the gas has not attained
a percolation threshold for the same reason as the gold deposits: once a percolation threshold is
reached, the reservoir would be breached and no resources would remain.

4.5 The relation between mass dimension and mass-radius scaling exponent

Mass dimensions and mass-radius scaling exponents have obvious applicability to resource
estimation (e.g. Barton and Scholz 1995; La Pointe, 1995). However, it is commonly hard to
measure the mass-radius scaling exponent because accurate data for “mass” (resources) is difficult
to obtain. The mass dimensions and mass-radius scaling exponents are similar for the three data
sets in which they could be compared. If this relationship was generally true, an approximate value
for the mass-radius scaling exponent can be given by the mass dimension.

5. Conclusions

Mass dimensions of hydrothermal gold deposits, volcanic vents, geothermal wells and gas wells
can be determined reliably from appropriate databases. How accurately these values reflect the
true distribution of natural resources is not known, but the low mass dimensions of hydrothermal
gold deposits compared to gas wells is consistent with a high degree of localization of the gold
deposits due to strong structural controls, compared to a relatively dispersed pattern of gas
accumulations, for which the widespread presence of the Marcellus shale as a source and a host is
one of the most important factors in determining their distribution. Mass dimensions of volcanic
vents and geothermal wells are intermediate between the gold and gas values. The mass-radius
scaling exponent (i.e. the variation of mass with distance including a measure of the resource) was
estimated for gold and gas data sets. This exponent is similar to the mass dimension; the latter could be used as a proxy for the mass-radius scaling exponent where resource estimates are not available. Percolation theory offers a framework for understanding the significance of the mass dimension and mass-radius exponents: the percolation threshold may not have been reached for the resources considered here.
